Abstract of the invention:

An electrically controlled light modulator device comprises at least one cell, where two deformable dielectric layers (12,13) meet at an interface, at least one of said layers consisting of viscoelastic relief forming gel (12). A first support electrode structure (14) and a second signal electrode structure (10) are arranged on separate sides of the dielectric layers (12,13) in order to create an electric field passing through said layers (12,13) and in order to create surface reliefs on the viscoelastic gel layer (12). According to the invention, a third enhancement electrode structure (40,50) is arranged in the proximity of the first signal electrode structure (10). Applying enhancement signal voltage between the enhancement electrode structure (40,50) and the signal electrode structure (10) concentrates locally the electric field passing through the two deformable dielectric layers (12,13) and therefore enhances the amplitude of the deformation of the viscoelastic gel layer (12).
